**Abstract**

Background and objective: Infusion of *Hibiscus sabdariffa* (*H. sabdariffa*) is a very popular drink in many parts of the world. Its phytochemical composition is associated to antioxidant, hypotensive, and antiatherosclerotic effects. However, the molecular mechanisms involved in these processes are not well known. The aim of this review was to report the scientific evidence supporting that regular use of *H. sabdariffa* decreases oxidative stress, atherosclerosis, lipid profile, and blood pressure.

Materials and methods: A search of recent publications was made in the following specialized electronic databases: Elsevier Journal, SciELO, FSTA, Science Direct, Springer Link, and NCBI. Results of research conducted in clinical trials in humans and in animal models and cell cultures were recorded. Keywords used included *H. sabdariffa*, oxidative stress, polyphenols, hypertension, atherosclerosis, and lipid profile.

Results: Results of the different articles suggested a possible therapeutic effect of *H. sabdariffa* extracts on oxidative stress, lipid profile, hypertension, and atherosclerosis thanks to its composition rich in phenolic compounds. Anthocyanins significantly decrease LDL oxidation, inhibit adipogenesis by regulating adipogenic signaling pathways and transcription factors, and modulate gene expression of certain microRNAs. No adverse events or side effects were reported.

Conclusions: Further more homogeneous, placebo-controlled studies in humans are needed to state that *H. sabdariffa* has therapeutic efficacy in humans.

Potencial terapéutico del Hibiscus sabdariffa: una revisión de las evidencias científicas

Resumen
Antecedentes y objetivo: La infusión de Hibiscus sabdariffa (H. sabdariffa) es una bebida muy popular en muchos lugares del mundo. Su composición fitoquímica se asocia a efectos antioxidantes, hipotensores y antiateroscleróticos. No obstante, no se conocen con profundidad los mecanismos moleculares implicados en estos procesos. El objetivo de la presente revisión fue describir las evidencias científicas que apoyan que el consumo regular de H. sabdariffa reduce el estrés oxidativo, la aterosclerosis, el perfil lipídico y la tensión arterial.

Material y métodos: Se realizó una búsqueda de publicaciones recientes en las siguientes bases de datos electrónicas especializadas: Elsevier Journal, SciELO, FSTA, Science Direct, Springer Link y NCBI. Se describieron los resultados de trabajos llevados a cabo en ensayos clínicos en humanos, modelos animales y cultivos celulares. Las palabras clave utilizadas fueron Hibiscus sabdariffa, estrés oxidativo, polifenoles, hipertensión, aterosclerosis y perfil lipídico.

Resultados: Los resultados de los diferentes artículos evidencian un posible efecto terapéutico de los extractos de H. sabdariffa sobre el estrés oxidativo, el perfil lipídico, la hipertensión y la aterosclerosis, gracias a su composición rica en compuestos fenólicos. Las antocianinas reducen significativamente la oxidación de la lipoproteína LDL, inhiben la adipogénesis mediante la regulación de las vías de señalización adipecócicas y factores transcripcionales, y modulan la expresión génica de determinados microARN. No se comunicaron acontecimientos adversos ni efectos secundarios.

Conclusiones: Son necesarios más estudios en humanos, estudios más homogéneos y controlados con placebo, para poder aseverar que H. sabdariffa posee eficacia terapéutica en humanos.

Introduction

Highly reactive free radicals (OFRs) are atoms or atom groups with an unpaired free electron. To achieve electrochemical stability, OFRs start a chain reaction that may damage biological macromolecules such as lipids, proteins, carbohydrates, and nucleic acids, and imbalance body homeostasis. Most OFRs result from normal cell metabolism. However, OFR production may also increase due to the metabolism of some exogenous substances, exposure to sun rays or ionizing radiation, pesticides, and heavy metals. Other factors affecting OFR production are associated with exposure to the action of some xenobiotics (chloroform, acetaminophen, carbon tetrachloride), tobacco smoke, or inadequate diet, either as excess harmful substances or as deficient antioxidants. All of these factors may cause excess OFRs in cells and increase susceptibility to the occurrence of patholgical conditions such as cancer, cell aging, atherosclerosis, high blood pressure (HBP) or hyperlipidemia.

HBP is a very important and common cardiovascular risk factor in modern society. In fact, HBP is one of the main risk factors for the development of cardiovascular disease together with smoking, dyslipidemia and, especially, high plasma levels of low density lipoprotein (LDL) cholesterol. To these should be added other predisposing risk factors, such as obesity and sedentary lifestyles, which exert their action through intermediate, causative or conditional risk factors. Cardiovascular diseases are the leading cause of death in Spain, and are responsible for almost 40% of all deaths. The mechanism starting HBP is unknown in 90% of cases, but there is evidence which appears to suggest that increased OFR production is related to its pathogenesis. In fact, it has been noted that individuals with HBP may experience an increase in blood levels of thiobarbituric acid, a marker of lipid peroxidation, and a reduction in antioxidant activities of the enzymes superoxide dismutase, glutathione peroxidase, and catalase. Moreover, Ward et al. found a decrease in non-enzymatic antioxidants, such as vitamin E and reduced glutathione, in patients with HBP. The pathogenesis of HBP has also been related to metabolic abnormalities, hormonal factors, and genetic changes. Specifically, it has been estimated from epidemiological and familial studies that the genetic component could cause approximately 40% of interindividual variability in HBP values. The central role of lipid metabolism in the homeostasis of hypertension justifies the extensive analysis made of the genetic varieties of genes that encode for proteins of this system. Maximum attention has been paid to polymorphisms related to functional changes in proteins encoding, for example, polymorphisms in apolipoprotein B and A and CD36 (cluster of differentiation 36), USF1 (upstream transcription factor 1), FADS3 (fatty acid desaturase 3), and GCKR genes (glucokinase regulatory protein). Ischemic heart disease and cerebrovascular disease or stroke are manifestations of atherosclerosis. The characteristic lesion is the atheroma plaque, consisting of lipid, fibrous tissue, and immune system cells. One of the earliest events in atherosclerosis is LDL accumulation in the arterial wall. One of the most widely accepted hypotheses to explain the development of atherosclerosis is slow oxidation of LDL trapped in the subendothelial space by the action of OFRs generated by vascular cells, demonstrating a close relationship between...
OFRs and LDL.\textsuperscript{29} The accumulation of lipoproteins in arterial endothelium triggers the activation of macrophage scavenger receptors, leading to the conversion of macrophages into foam cells. Progressive foam cell accumulation contributes to lesion progression.\textsuperscript{10}

Plants and animals have endogenous antioxidant systems to remove excess production of OFRs, such as glutathione, vitamin D and vitamin E, catalese, superoxide dismutase, and several peroxidases.\textsuperscript{31} Glutathione peroxidase, superoxide dismutase, or the catalase in peroxisomes are endogenous or primary antioxidant enzymes able to metabolize OFRs generated in cellular redox processes. By contrast, alpha lipoic acid, vitamins C, E and A, and polyphenols are considered non-enzymatic or secondary antioxidants able to directly destroy OFRs.\textsuperscript{32}

Polyphenols are a very numerous and heterogeneous group of molecules which share the characteristic of having several phenol groups in their structures. Many epidemiological studies support the antioxidant properties of polyphenols,\textsuperscript{33-38} although their antioxidant capacity depends on their bioavailability and absorption. In turn, this is greatly affected by several factors such as climate, type of soil, type of culture, and sun exposure, amongst others.\textsuperscript{37} Most polyphenols are metabolized by colonic microorganisms before being absorbed, and the products resulting from this fermentation are partly responsible for their systemic effects.\textsuperscript{38-42} The antioxidant capacity of polyphenols accounts for their vasodilating, antithrombotic, anti-inflammatory, and antiapoptotic actions,\textsuperscript{43} and also for their antilipemic,\textsuperscript{44,45} and antiatherogenic properties.\textsuperscript{46} The antioxidant activity of polyphenols is tenfold higher than that of vitamin A and 100-fold higher than that of vitamin E or carotenoids.\textsuperscript{47} More specifically, there are studies suggesting that phenolic compounds may attenuate the oxidation of LDL and high density lipoproteins (HDL).\textsuperscript{48-53} In healthy humans, it has been suggested that resveratrol, one of the main phenolic compounds in wine, could prevent the oxidation of LDL and decrease lipid hydroperoxide levels.\textsuperscript{54} Recently, Castaner et al.\textsuperscript{55} showed that phenolic compounds in olive oil could decrease LDL oxidation and the expression of the CD40L (CD40 ligand) gene, as well as genes related to inflammation processes in humans. The molecular processes associated with the antilipemic and antiatherogenic properties of polyphenols result from their ability to regulate the expression of different genes associated with the immune system and energy metabolism, and/or from their epigenetic regulation capacity\textsuperscript{56} through the induction of changes in the methylation pattern of DNA CpG islands.\textsuperscript{56,57} histone acetylation,\textsuperscript{58} and modulating the expression of some miRNAs.\textsuperscript{59} In this regard, for example, quercetin, the active component of Hibiscus sabdariffa (H. sabdariffa), has been reported to inhibit the activity of histone acetyltransferase in the promoter region of genes associated with the manifestation of inflammation.\textsuperscript{58} Joven et al.\textsuperscript{60} used hyperlipidemic mice with LDL receptor deficiency to assess the role of polyphenols in the prevention of liver disease by regulating the expression of hepatic miRNAs miR103/107 and miR122. In their results, these authors emphasized that the oral administration of polyphenols reverted changes induced in non-specific miRNAs miR103/107 after chronic polyphenol intake, and the lack of response of the specific miRNA miR122, speculating about the potential implication of polyphenols in cell metabolism. The authors reported that modulation of microRNA expression may be a significant and additional intervention mechanism in chronic diseases. Crozier et al.\textsuperscript{61} have shown that polyphenolic extract-miRNA specificity may exist, given the potential variety of different structures and compositions of extracts, depending on their botanical origin. Additional studies in humans are however needed to clarify the epigenetic effects of polyphenols.

H. sabdariffa has a high polyphenol content.\textsuperscript{62} It is also called Jamaica sorrel, roseelle, or karkade, and belongs to the malvaceae family native to tropical Africa, although it is cultivated in Mexico, Central America, and south-east Asia. It is an annual herbaceous plant living in dry, subtropical, mountain climates. Its calyces, fleshy and of a vivid red color, have high concentrations of l-ascorbic, arachidic, citric, stearic, and matic acids, in addition to pectins, phytosterols (e.g. β-sitosterol and ergosterol) and polyphenols.\textsuperscript{52} Peng et al.\textsuperscript{63} in their research to assess the hypoglycemic and hypolipidemic effect of the polyphenolic extract of H. sabdariffa, found at least 18 different polyphenolic compounds in H. sabdariffa (Fig. 1). Commercial preparations of concentrates of calyces, and occasionally leaves, of H. sabdariffa are very commonly found as fluid or powder for the preparation of instant drinks or infusions.\textsuperscript{64} In addition, its widespread use as a herbal treatment in popular medicine has led to a high acceptance rate by the general population,\textsuperscript{65} especially in countries such as the United States,\textsuperscript{66} Mexico,\textsuperscript{67-69} some eastern African countries,\textsuperscript{70-72} Iran,\textsuperscript{71} India,\textsuperscript{73} Taiwan,\textsuperscript{63} Brazil,\textsuperscript{74} and Greece.\textsuperscript{75} The ethnototanical studies available usually describe the origin and parts of the plant used, the properties attributed to it and the form of preparation, without specifying the dosage. No demographic studies supporting the role of the plant in disease prevention have been found.\textsuperscript{76} On the other hand, scientific studies have shown that the antioxidant effects of polyphenols in H. sabdariffa have an antiatherogenic action and decrease hypertension and hyperlipidemia with no reported adverse events or side effects in animals and humans.\textsuperscript{45-67,72-79}

The purpose of this paper was therefore to collect and unify the evidence showing that regular consumption of H. sabdariffa may have a beneficial effect on human health because of the antioxidant, antihypertensive, and lipid-lowering effects of its phenolic components.

Materials and methods

In this review, a search for recent publications was made in the following specialized electronic databases: NCBI, Elsevier Journal Finder, SciELO, ScienceDirect and Springer-Link. Results from studies conducted in vitro, in animal models and in humans were collected. Reviews collecting and analyzing the effectiveness of H. sabdariffa in given treatments, such as antihypertensive and lipid-lowering therapies, amongst others, and articles referring to the phytochemical, pharmacological, and toxicological aspects of H. sabdariffa were also included. The concepts of oxidative stress, antioxidant capacity, hyperlipidemia, high blood pressure, and atherosclerosis were also analyzed to describe in more detail the molecular mechanisms of H. sabdariffa. The keywords used included: H. sabdariffa, oxidative stress,
polyphenols, high blood pressure, atherosclerosis, and lipid profile.

A total of 104 articles were reviewed in preparing this paper. The articles selected were divided into the following categories: (1) generic articles on the pharmacological, chemical, and ethnobotanical properties of H. sabdariffa; (2) articles on the relationship between the consumption of H. sabdariffa and oxidative stress, and its antioxidant, antihypertensive, hypolipidemic, and antiatherosclerotic potential.

Results and discussion

Studies analyzing the therapeutic effects of H. sabdariffa used in this review are grouped into three tables. In each table, the part of H. sabdariffa used and the procedure to obtain the extract of H. sabdariffa are given, as well as a summary of the most relevant results and conclusions. Tables 1 and 2 show the results of studies conducted on different cell lines and animal models respectively. Table 3 shows the results of studies conducted in humans.

The part of the plant used and the extraction method are important because the different parts of H. sabdariffa, their color, the harvesting procedure, and the method used to extract its phytochemical components appear to have a great influence on the volatile composition of the extract, which has an influence on dosage. It should be noted, for instance, that a higher antioxidant capacity has been found in flowers harvested 35 days after maturation as compared to more immature flowers. The extraction of calyx components with ethanol promotes the antioxidant capacity of H. sabdariffa as compared to ethanol extraction from leaves or aqueous extraction from both parts. Aqueous extraction is, however, of the greatest interest when testing the effectiveness of the different parts of the plant because it is the traditional preparation procedure and is therefore of greater significance with regard to its implications for public health.

Specifically, Table 1 shows studies conducted on different cell lines. Various cell lines were selected to conduct the experiments, ranging from rat hepatocytes, mouse macrophage cell lines RAW264.7 and J774A.1, and preadipocyte cell line 3T3-L1 to human leukemia cells HL-60. Most of these studies focused on the evaluation of the antioxidant capacity of H. sabdariffa derived from either the effect of its anthocyanin content, the action of protocatechuic acid, or the biological action of other H. sabdariffa molecules. Using cell lines of rat hepatocytes pretreated with the cytotoxic compound t-BHP, Tseng et al. showed the antioxidant effect (especially cytotoxic and genotoxic) of the different soluble fractions of H. sabdariffa through free radical removal and the inhibition of unscheduled DNA synthesis. The antioxidant effect of H. sabdariffa was mainly attributed to anthocyanins. The

antiatherosclerotic capacity of anthocyanins in *H. sabdariffa* through the inhibition of LDL oxidation was analyzed by Kao et al. using mouse macrophages. Their objective was to assess anthocyanin action in foam cell formation and in the expression of the predominant receptor gene for oxidized LDL, CD36, and its transcription factor PPAR-gamma (peroxisome proliferator-activated receptor gamma). The authors showed that *H. sabdariffa* inhibits the absorption of oxidized LDL by macrophages by decreasing the expression of the CD36 receptor gene. Chang et al. similarly reported the *in vitro* role of anthocyanins in *H. sabdariffa* in the inhibition of LDL oxidation and, thus, in the prevention of atherosclerosis. Kim et al. analyzed the capacity of *H. sabdariffa* extract for the inhibition of adipocyte differentiation and its potential benefit in obesity prevention. They suggested that *H. sabdariffa* may inhibit adipogenesis through the inhibition of three different pathways: (1) the inhibition of adipogenic transcription factors C/EBPα (enhancer binding protein) and PPAR-gamma (peroxisome proliferator-activated receptor gamma), (2) the inhibition of PI3K (phosphoinositide 3-kinase) pathways, and (3) the inhibition of metabolic pathways associated with MAPK (mitogen-activated protein kinase). Treatment with *H. sabdariffa* extract during the adipogenic differentiation process showed a significant reduction in protein and mRNA expression of factors C/EBPα and PPAR-gamma. The authors also reported a decrease in the mRNA of leptin, a hormone regulating intake and energy expenditure and which is partially activated by C/EBPα at the transcriptional level. It should also be noted that the *H. sabdariffa* extract inhibited PI3K phosphorylation and expression during adipogenesis. Because of these results, the authors stated that *H. sabdariffa* is able to block the PI3K and MAPK signaling pathways and inhibit transcriptional factors during the early differentiation phases of adipocytes. Based on all of the foregoing, the authors postulated that *H. sabdariffa* extracts are beneficial for obesity prevention and may lead to body fat loss *in vivo*. To sum up, Table 1 clearly states the antioxidant effect of *H. sabdariffa*, mainly attributed to anthocyanins, which leads one to hypothesize about its capacity to take up OFRs and, among other properties, the inhibition of unscheduled DNA synthesis and the epigenetic changes which could be derived from them. These results open the way to continuing research in animal models and humans to validate the postulated hypotheses.

In the animal models in Table 2, healthy animals or animals previously manipulated to induce diabetes or atherosclerosis, hypercholesterolemia or hyperlipidemia, or high blood pressure to test the effects of *H. sabdariffa* consumption were used. Ajiboye et al. reported the potential of *H. sabdariffa* to take up the radicals di-phenyl-2,4,6-trinitrophenyl iminoazaniam and 2,2-diphenyl-1-pirclyhydrizyl at a dose of 2 mg/mL of anthocyanin extract from *H. sabdariffa*, and to take up superoxide ion and hydrogen peroxide at a concentration of 1 mg/mL. The antioxidant potential of *H. sabdariffa* was analyzed in blood and liver of albino rats. Liu et al. showed that doses of 200, 400, and 600 mg/kg of aqueous extract of *H. sabdariffa* flowers decreased lipid peroxidation and increased catalase activity and GSH levels in plasma and liver tissue from mice. Ali et al. reported that doses of 200 mg/kg of aqueous extract of calyces restored to normal the biochemical indices of...

Therapeutic potential of *Hibiscus sabdariffa*

Liver damage caused by acetaminophen in mice, showing the capacity of *H. sabdariffa* to prevent liver damage. Olatunji et al. showed that chronic intake for 28 days of 1–1.5 mg/kg/day of aqueous extract of *H. sabdariffa* petals significantly decreased plasma LDL levels in experimental rats. Only the 1.5 mg/kg/day doses of aqueous extract of *H. sabdariffa* petals showed a significant decrease in plasma total cholesterol levels, with no significant changes in HDL or total triglyceride levels. No relevant changes were seen either in serum HDL levels after the use of *H. sabdariffa* in experiments conducted in models of hypercholesterolemia, hyperlipidemia, or induced obesity, but significant improvements occurred in total cholesterol, LDL and/or total triglyceride levels. In parallel, Hirunpanich et al. also showed its effectiveness at doses higher than 250 mg/kg/day after 6 weeks of intake of aqueous extract of calyces. These same authors noted that doses higher than 1000 mg/kg were not associated with greater effectiveness, which suggested saturation of the lipid-lowering effect. The authors showed the pharmacological dose of aqueous extract of calyces to range from 250–1000 mg/kg/day. By contrast, Ochani and D’Mello showed that doses of 500 mg/kg/day of alcoholic extract of leaves and calyces and 400 mg/kg/day of aqueous extract of flowers, respectively, not only decreased total cholesterol, LDL and total triglyceride levels in serum, but also increased HDL levels. In rat models with induced diabetes, alcoholic extracts of *H. sabdariffa* flowers or calyces caused a reduction of serum levels of total cholesterol, LDL and/or total triglycerides. So far, there have been no articles relating the use of *H. sabdariffa* to epigenetic changes. Further studies are therefore needed to understand the molecular mechanisms associated with the use of *H. sabdariffa* and disease pathogenesis, particularly in humans. Continuing with the study of the effects of *H. sabdariffa* on the regulation of energy and cell metabolism, Chen et al. worked with an atherogenic rabbit model to assess the antiatherosclerotic and lipid-lowering effect of *H. sabdariffa* extracts. Histologically, they showed that exposure for 10 weeks to doses of a 0.5–1%/diet of *H. sabdariffa* aqueous extract resulted in decreased foam cell formation and the inhibition of blood vessel calcification, as well as serum total cholesterol, LDL, and triglyceride levels. The authors concluded that the antiatherosclerotic activity of *H. sabdariffa* is related to the prevention of LDL oxidation in the arterial wall and that its consumption may be beneficial for decreasing disease incidence. Wang et al. emphasized antioxidative and antiapoptotic mechanisms as a potential explanation for decreases in total cholesterol, LDL, and total triglyceride levels. Lee et al. reported increased catalase and glutathione activities at doses of 200 mg/kg and decreased lipid peroxidation as mechanisms for regulating plasma lipid levels. The results of animal studies show the antihypertensive and antioxidant effects of *H. sabdariffa*. However, the results on the effect of *H. sabdariffa* intake on cholesterol metabolism, and thus on the parameters of the associated diseases, are more variable. In this regard, the heterogeneity of the results in terms of HDL levels after the consumption of *H. sabdariffa* should be noted, because although HDL levels significantly increased with high doses of *H. sabdariffa* extract in a few studies, they did not usually change. A single conclusion is difficult to reach because of the high diversity in the methods used, the number of subjects used in each group, and the doses used in the different experimental protocols.

Table 3 shows the results of studies in humans. Observational studies with and without placebo, epidemiological, interventional, randomized case–control studies with and without placebo, and randomized studies are shown.

The different studies assessed the antioxidant, lipid-lowering, and antihypertensive effects of *H. sabdariffa* in healthy subjects, patients with metabolic syndrome, diabetic patients with mild hypertension, prehypertensive and mildly hypertensive subjects, hypertensive patients previously given standard antihypertensive medication, and subjects with hyperlipidemia. Frank et al., in a study on the antioxidant capacity of *H. sabdariffa*, administered 10 g of *H. sabdariffa* as an infusion to an experimental group of eight healthy subjects. After intake, blood and urine were collected from the participants for 24 h. The authors showed a significant decrease in malondialdehyde, an oxidative stress biomarker, and a marked increase in the antioxidant potential of human plasma and urine. They also found a significant increase in urinary excretion of hippuric acid, which showed a high biotransformation of the *H. Sabdariffa* polyphenols ingested and pointed to the role of colon microbiota in this transformation. Gurrola-Diaz et al. focused their study on the preventive and improving effects of *H. sabdariffa* on the lipid profile in subjects with or without metabolic syndrome. The most significant data from this study showed that subjects with evidence of metabolic syndrome and who had received experimental treatment with dry extracts of *H. sabdariffa* calyces had significant decreases in blood glucose and total cholesterol levels, increased HDL levels, and an improvement in the total triglycerides/HDL ratio, an insulin resistance marker. The authors showed that anthocyanins in *H. sabdariffa* could regulate adipocyte function, as postulated by Tsuda. Similarly, Mohagheghi et al. subsequently analyzed the short-term efficacy of extract from *H. sabdariffa* calyces on the reduction of serum glucose and lipid levels in hypertensive patients with a history of conventional antihypertensive treatment versus intake of the same amount of black tea. Increased levels of total cholesterol and lipoproteins bound to cholesterol (LDL and HDL) were seen with both treatments. Increases in total cholesterol and HDL levels as compared to baseline were significant in both cases. No changes harmful for health were seen in cholesterol, total triglycerides, serum creatinin, Na+, or K+ within 15 days of discontinuation of the medication. They, therefore, concluded that *H. sabdariffa* is a safe medicinal plant. Kurian et al. could not show the lipid-lowering effect of *H. sabdariffa* leaves in patients on a standard diet and physical exercise. The authors reported decreased body weight and LDL and total triglyceride levels in control and treated patients, and suggested that the results seen were secondary to exercise and diet.

As regards the antihypertensive effect of *H. sabdariffa*, McKay et al. showed that daily intake of three cups of tea of *H. sabdariffa* significantly decreased systolic pressure in prehypertensive and moderately hypertensive subjects. Ajay et al. showed that the antihypertensive effect with vasodilating effects and/or decreased heart rate of
*H. sabdariffa* could be related to its anthocyanin-rich composition. Wahabi et al., in a meta-analysis of the quality of studies conducted on the effectiveness of *H. sabdariffa* in the treatment of hypertension in prehypertensive or mildly hypertensive subjects, reported that no adequate scientific evidence was available to validate the antihypertensive properties of *H. sabdariffa*. In fact, these authors stated that they were studies of inadequate quality, short duration, and high methodological diversity, which did not allow them to adequately assess the potential adverse effects of continued *H. sabdariffa* intake.

The results given in the different tables suggest that *H. sabdariffa* has antioxidant potential and the capacity to attenuate high blood pressure and the diseases associated with obesity and diabetes such as nephropathy, atherosclerosis, and cardiovascular diseases. The diversity of the effects of *H. sabdariffa* seen in humans may be attributed to the different polyphenol concentrations in *H. sabdariffa* and other concomitant nutrients, to the solvents used for extraction, to the time and form of administration, as well as to the small number of studies available, methodological differences (e.g. the use of black tea as control instead of placebo), different population sizes, and inter-individual heterogeneity.

Finally, some authors suggest that *H. sabdariffa* extracts have a low grade of acute toxicity with a mean lethal dose (LD₅₀) ranging from 2000 to more than 5000 mg/kg/day. However, a possible adverse effect has been seen in the liver at high doses (Table 4). Akindahunsi and Olaleye reported the occurrence of liver toxicity with chronic intake of doses higher than 3000 mg/kg of extract of *H. sabdariffa* calyces. Fakaye et al. pointed out that long-term consumption of high doses of flower extract may cause toxic reactions which may even be confused with episodes of chronic hepatitis. In fact, doses of 2000 mg/kg/day for 90 days induced severe weight losses and diarrhea in their experimental animals. By contrast, experiments using doses ranging from 50 to 100 mg/kg led to the hypothesis that ethanolic and aqueous fractions of extracts from *H. sabdariffa* flowers could have the potential to become pharmacological entities for stimulating immunity.

**Conclusions**

The traditional consumption of *H. sabdariffa* as an infusion has been related to different therapeutic properties. Specifically, the results of this review suggest that *H. sabdariffa* is able to take up free radicals inhibiting, for example, LDL oxidation. In addition, it appears that daily consumption of *H. sabdariffa* extract can significantly improve blood pressure in prehypertensive and mildly hypertensive patients and patients with type 2 diabetes. On the other hand, the use of *H. sabdariffa* can improve lipid profile, reducing serum levels of total cholesterol, LDL, and total triglycerides. Anthocyanins in *H. sabdariffa* have been shown to be able to inhibit LDL oxidation and possibly to decrease the risk of atherosclerosis. Although different studies have attempted to show the antioxidant, antihypertensive, and lipid-lowering effects of regular consumption of *H. sabdariffa* in humans and animal and cell models, the cellular, biological, and epigenetic mechanisms of the specific effects of *H. sabdariffa* have yet to be elucidated. The results published to date do not allow us to define any dose of *H. sabdariffa* with regard to its therapeutic properties. The lack of homogeneity in the experimental design of the different studies, as well as the low number of subjects and their heterogeneity, could be some of the causes of the lack of consistency in the results. However, the results represent interesting findings which should be thoroughly analyzed, because understanding of the distribution and function of polyphenols from *H. sabdariffa* in patients with different conditions may be helpful for achieving effective treatment. Continued research in the field of alternative non-drug treatments, such as functional foods, is also required. Only a limited number of *H. sabdariffa* extracts have been tested to date, and since the effects of different components are not equivalent, the results cannot be generalized. Future large scale studies with control of doses, active components, bioavailability, and other critical variables will therefore be crucial to provide the scientific evidence required to ascertain the efficacy of any therapeutic approach with *H. sabdariffa* and its doses.

**Conflict of interest**

The authors state that they have no conflicts of interest.
