**Acute hepatitis as a manifestation of secondary syphilis**

**Hepatitis aguda como manifestación de sífilis secundaria**

The most common causes of acute hepatitis are alcohol and hepatotropic viruses. However, other much less common infectious agents can also cause acute hepatitis in the context of systemic diseases. We present the case of a patient diagnosed with secondary syphilis with hepatic involvement.

This was a 26-year-old homosexual male with no relevant previous medical history. He went to Accident and Emergency with a two-week history of asthenia, epigastric pain, pharyngeal discomfort and mucocutaneous jaundice. His regular partner had been diagnosed with syphilis two months earlier, so the patient had also had serology for *Treponema pallidum* at that time, which was negative. He reported no fever, altered bowel habit, recent travel, contact with small children, tattoos or previous transfusions, use of potentially hepatotoxic substances or ingestion of spoiled food.

On physical examination, an ulcer was found on the left tonsil with a blackish fibrinous base (Fig. 1), in addition to jaundice. There were no signs of lymphadenopathy, skin lesions, genital lesions or neurological alterations.

Blood tests showed abnormal liver function tests, predominantly with cholestasis [aspartate aminotransferase (AST): 176 IU/l; alanine aminotransferase (ALT): 371 IU/l; gamma-glutamyl transpeptidase (GGT): 540 IU/l; alkaline phosphatase (AP): 1032 IU/l; and total bilirubin of 7.9 mg/dl] with complete blood count, coagulation and other basic clinical biochemistry normal. Abdominal ultrasound showed no abnormal findings.

One month before attending Accident and Emergency, the patient had been assessed in Hepatology Outpatients for non-specific malaise with slight elevation of transaminases, and a full investigation for liver disease was requested. Serology for common hepatotropic viruses (hepatitis A, B, C and E) as well as HIV, autoimmunity (ANA, AMA, anti-LKM and smooth muscle antibodies), iron profile, ceruloplasmin and alpha-1 AT were all negative. Serology for syphilis was repeated, resulting in positive IgG, rapid plasma reagin (RPR) test 1/32 and positive *T. pallidum* haemagglutination assay (TPHA). A sample was taken of the ulcer on the left tonsil, interpreted as syphilitic chancre, with *T. pallidum* confirmed in the genome amplification.

As secondary syphilis with hepatic involvement was suspected, treatment was prescribed with penicillin G benzathine. The patient made good progress, with improvement both clinically and analytically.

Syphilis is a sexually or vertically transmitted disease caused by the spirochete *T. pallidum*. Syphilitic liver involvement is very uncommon (<1% of cases) and can occur in the secondary or tertiary phase of disease due to multiplication and haemagenous spread of the spirochete to the liver.

In the secondary syphilis phase, cholestasis occurs, with a characteristic elevation of alkaline phosphatase; this is usually accompanied by pyrexia, the typical palmpoplantar rash and even nephrotic syndrome, although all three signs do not always have to be present. In the tertiary phase, the characteristic lesions are syphilitic gummas, most common in the right lobe of the liver and generally asymptomatic, unless they cause compression leading to Budd-Chiari syndrome.

The diagnosis can be established in the presence of abnormal liver function tests, positive serology and improvement after antibiotic treatment. The liver biopsy findings are not pathognomonic (perportal necrosis, endotheliitis, cholangitis or pericholangitis) unless the spirochete is detected in the hepatic lobule, which is very uncommon. Therefore, although some authors consider it advisable to perform a liver biopsy for the definitive diagnosis, it does not seem to be essential. In most of the patients described in the literature, syphilis coexists with other sexually transmitted diseases (HBV, HCV, HIV, etc.), so it has to be taken into account that finding one cause of liver disease does not exclude others.

The treatment of syphilitic hepatitis consists of administration of penicillin G benzathine, or doxycycline or macrolides in the case of allergy to beta-lactams. In the second week of treatment, jaundice (an idiosyncratic reaction known as Jarisch-Herxheimer) with uncertain pathophysiology may develop, but it clears up without sequelae in virtually all cases.

In our patient, liver involvement represented an unusual manifestation of secondary syphilis, as no pyrexia, palmpoplantar rash or nephrotic syndrome were detected. Nor did he have any other concomitant sexually transmitted disease. The previous epidemiological history in his partner (not revealed initially by the patient), the cholestasis with elevation of alkaline phosphatase and, finally, the positive serology, pointed to the diagnosis. The atypical location of the syphilitic chancre on the tonsil was interesting and confirms the importance of a thorough history and physical examination. As the genome amplification was positive for *T. pallidum* and the patient had an excellent response to the antibiotic treatment, liver biopsy was not considered necessary.

In conclusion, liver dysfunction related to secondary syphilis is an uncommon occurrence, but should be suspected in at-risk patients. Liver biopsy is not considered.
essential for diagnosis in all cases. In the majority of patients, the outcome is excellent once they start treatment with penicillin G benzathine.

Oesophageal intramural pseudodiverticulosis is a rare benign disease, initially described by Mendel in 1960. In retrospective radiological studies, the condition was found in 0.15% of the oesophageal images. There are just over 250 published cases, with a slight predominance in males over the age of 50. It consists of small sac-like invaginations in the oesophageal wall with segmental (predominantly proximal) or diffuse involvement. The pathogenesis is unknown,

Dysphagia caused by intramural oesophageal pseudodiverticulosis: An unusual endoscopic finding

Disfagia por pseudodiverticulosis esofágica intramural: unasual hallazgo endoscópico

We present the case of a 42-year-old female patient, who was referred to our department with a five-year history of progressively worsening oesophageal solid-food dysphagia. She reported repeated episodes of food impaction, which passed spontaneously without the need for extraction by endoscopy. Her previous medical history included HIV for 10 years, for which she partially adhered to treatment, an episode of oesophageal candidiasis three years prior to the consultation for which she received antifungal treatment which partially improved the symptoms, alcohol consumption of 200 g/day for 10 years and smoking. An upper GI video-endoscopy was performed which showed sectors with dilated lumen and other narrow sectors, with no food content. Multiple small holes were found, 2–4 mm in diameter, of different depths, with signs that the mucosa was indurated (Fig. 1). Multiple biopsies were taken with nonspecific results, but eosinophilic oesophagitis was ruled out. Treatment was started with proton pump inhibitors with improvement in the dysphagia at 24 h. The patient was discharged from hospital and followed up by infectious diseases and gastroenterology.
