Factors associated with reported hepatitis C and HIV among injecting drug users in ten European cities

Joan Carlos March, Eugenia Oviedo-Joekes and Manuel Romero

BACKGROUND. To analyze self-reported prevalence of HCV and HIV in a sample of socially excluded injecting drug users, as well as factors associated with the presence of these diseases.

METHODS. Cross-sectional study. Data were collected with a structured, face-to-face questionnaire by outreach workers and privileged access interviewers in 1131 participants who had injected heroin and/or cocaine over the past year (71.5% men; mean age, 30 years) from Seville and Granada, Spain; Cologne, Germany; Vienna, Austria; Brussels, Belgium; Athens, Greece; Dublin, Ireland; London, England; Lisbon, Portugal and Perugia, Italy.

RESULTS. Among the total sample, 595 (52.6%) participants reported HCV-positive status and 143 (12.6%) HIV-positive status. Multivariate analysis for HCV showed that women are at less risk than men, and that longer drug use, injecting while in prison, sharing needles, and reported positive status for tuberculosis, HBV, HIV or sexually-transmitted disease are positively associated with HCV. Participants reporting positive HIV status were generally older, had injected drugs while in prison, had completed less than 8 years of schooling, were divorced, did not have regular employment, and declared infection with tuberculosis, sexually-transmitted disease and HCV.

CONCLUSIONS. The highest incidences of HCV and HIV were reported by participants in a poorer social and health situation. Drug addicts must cope not only with their addiction but also with the process of social exclusion they are immersed in. To the greatest extent possible, any course of action for this group should be built into integrated, coordinated plans that take a broad approach to the main issues involved.

Key words: Injecting drugs. HIV. HCV. Social exclusion.

Factores asociados a la hepatitis C e infección por VIH documentadas entre drogodependientes por vía intravenosa en 10 ciudades europeas

OBJETIVOS. Analizar la prevalencia del virus de la hepatitis C (VHC) y del virus de la inmunodeficiencia humana (VIH), según autoinformes, en una muestra de usuarios de drogas por vía inyectada en situación de exclusión social, así como los factores asociados a dichas enfermedades.

MÉTODO. Estudio transversal. Los datos se recogieron con un cuestionario estructurado, cara a cara, llevados a cabo por entrevistadores expertos en el campo de estudio, y con acceso privilegiado a la muestra (iguales). La muestra se compone de 1.131 participantes que habían usado heroína y/o cocaína el último año por vía inyectada (71,5% hombres; edad media de 30 años), en las ciudades de Sevilla y de Granada, España; Colonía, Alemania; Viena, Austria; Bruselas, Bélgica; Atenas, Grecia; Dublin, Irlanda; Londres, Inglaterra; Lisboa, Portugal y Perugia, Italia.

RESULTADOS. 595 (52,6%) participantes dijeron ser positivos al VHC y 143 (12,6%) al VIH. Los análisis multivariantes para el VHC muestran que las mujeres están a menor riesgo que los varones, y que un uso más prolongado de drogas, haberse inyectado en prisión, compartir agujas, y referir ser positivo a la tuberculosis, VIH, y enfermedades de transmisión sexual (ETS) se asocian positivamente al VIH. Los participantes que refieren ser VIH positivos son generalmente de mayor edad, se han inyectado drogas en prisión, tienen menos de 8 años de escolarización, están divorciados, no tienen empleo regular, y declaran ser positivos a la tuberculosis, los ETS y VIH.

CONCLUSIONES. Las incidencias más altas de VHC y del VIH fueron referidas por los participantes que se encuentran en una peor situación social y de salud. Las personas toxicodependientes no solo deben hacer frente a su adicción sino también al proceso de exclusión social que generalmente lo acompanieda a ésta. Cualquier orientación de estos grupos debería, en la medida de lo posible, llevarse a cabo dentro de un plan coordinado e integrado que tenga en cuenta los principales aspectos que deben ser abordados.

Palabras clave: Drogas inyectadas. Hepatitis C. VIH. Exclusión social.

Introduction

The use of intravenous drugs is one of the main risk behaviors for the transmission of hepatitis C virus (HCV) and human immunodeficiency virus (HIV). As a result, their is a high prevalence of these infections among intravenous drug users (IDUs), with estimates of 30-60% for HCV and 1-30% for HIV.

The prognosis of HIV disease has improved considerably since 1996 when highly active antiretroviral therapy...
Hepatitis C infection is five times more widespread than HIV, and has remained unchanged even in communities where the rate of HIV infection has fallen. In industrialized countries HCV infection has become one of the major health problems among current and former IDUs. Although the sexually-transmitted infection rates of HCV are lower than those of HIV, HCV transmission through injection is much more effective. Thus, IDUs are one of the main groups affected by this disease. In the acute phase, hepatitis C has few or no symptoms, but serious diseases, such as hepatic cirrhosis or carcinoma, can develop over a series of decades. This asymptomatic course makes it difficult to stage the disease, particularly when there has been no monitoring, and this prevents the implementation of healthcare measures.

With the increase in life expectancy of HIV-infected persons, HCV appears as the most frequently associated pathogen. The prevalence of HCV infection among individuals living with HIV is around 40%, with some studies reporting up to 94%. It has been suggested that HIV and HCV co-infection leads to higher mortality rates and a greater likelihood of sexual or mother-to-child transmission of HCV, as well as an accelerated course of HCV infection.

In view of the above factors, former and current IDUs, whether regular or only occasional users, constitute a vulnerable group that requires an ongoing review of prevention strategies, healthcare provision, treatment and damage limitation via a HIV and HCV program. In general, IDUs are a heterogeneous group and depend on the social circumstances of their environment, the drug market, type of drug use, etc. This often makes it difficult to locate and study IDUs and determine the incidence of HIV and HCV in this population. This study has compiled information from the streets through interviews with the most socially marginal groups to determine drug use patterns, risk behavior, and the incidence of infectious diseases. The aim of this effort is to analyze the self-reported prevalence of HCV and HIV in a sample of socially excluded injecting drug users, as well as factors associated with the presence of these diseases.

Method

Design and study population

This is a cross-sectional study on the risk behavior and life styles of socially excluded drug users. The data considered in this paper encompassed within a European research project (Excludes project) on risk behavior and life styles among socially excluded persons, drug users, heterosexuals, and homosexuals at risk for HIV/AIDS in Europe. The following cities took part in this project: Seville and Granada, Spain; Cologne, Germany; Vienna, Austria; Brussels, Belgium; Athens, Greece; Dublin, Ireland; London, England; Lisbon, Portugal and Pisa, Italy. The initial sample included 1879 participants, mainly heroin and/or cocaine users (92.3%), with a mean age of 30.19 years. Only those participants that had consumed heroin, cocaine or any derivative of these substances continuously over the past year were considered for the present study.

Participants and data collection

The sample contained 1133 participants (71.5%) men with a mean age of 30 years who had injected heroin and/or cocaine over the past year. Data were compiled between July and October 1998 (England, Italy and Portugal) and between July and October 2000 (Austria, Belgium, Greece, Ireland, Germany and Spain). Structured, face-to-face interviews were held, using a World Health Organization questionnaires for risk behavior for HIV transmission and drug use that was adapted to local conditions and the aims of the study. The interviews were conducted by outreach workers and privileged access interviewers, i.e. former drug users, in the locations where participants with the required profile were most frequently found (social service centers, town hall, street, squares and other common meeting points). This approach, combined with the “snowball” technique, allowed contact with a population that did not use regularly or at all the available social and health services, from which drug users are often recruited.

Statistical analysis

Two variables, the self-reported serological status for HCV and for HIV, were analyzed. The three possible replies for those variables were positive, negative or unknown. Information on HCV was compiled by asking participants whether they formerly or currently had the disease. For HIV, subjects were asked whether they had ever been tested for HIV, and whether they had ever had a blood test for HEAIDS and, if so, what the result had been. First, a descriptive analysis was made to ascertain the final HCV and HIV case count overall and for each country involved in the project. Comparisons were made with the following groups of variables to provide insight into which factors are linked to HCV and HIV infection: sociodemographic characteristics, history of treatment for drug addiction, and risk behavior for acquiring HCV and related diseases. ANOVA was used to enable comparison between the continuous variables (age, age at onset of drug use, and how long heroin and/or cocaine had been used), and the chi-squares test was used for the nominal variables. Lastly, a stepwise binary logistic regression model was developed between the independent variables and HCV or HIV self-reported positive versus negative status. Variables with a P-value of < 0.05 were entered in the model, and retained with a P-value of < 1. Gender, age and country were forced into the model regardless of their significance. The Windows SPSS statistical package was used to perform the analysis.

Results

Among the 1131 injecting drug users, 595 (52.6%) reported HCV-positive status and 143 (12.6%) HIV-positive status (table 1). One hundred thirty-six participants (12%) stated they were unaware of their HCV status, and 247 (21.4%) had never been tested for HIV. Prevalence of reported HCV-positive status was over 50% in Ireland, Germany, Portugal, and Spain. Belgium and Italy had the highest percentages of patients unaware of HCV status. No German or Greek participants reported HIV-positive test results and a large proportion of participants from Portugal, England, Belgium and Ireland claimed they had
never been tested. The highest HIV-positive rates were reported in Spain (50.4%), Ireland (24.6%) and Italy (16%). The total reported HCV-positive and HIV-positive cases among those who knew their status was 59.8 and 16.2, respectively.

The reported prevalence of HCV and HIV infections increased with age and years of drug use, and showed a statistically significant association (table 2). Chi-square comparisons in tables 3, 4 and 5 summarize the variables that were significantly associated with reported HCV and HIV status, and the prevalence of these infections at each level. High prevalences of HCV and HIV were found in participants who had completed less than 8 years of education, were widowed, had injected drugs while in prison, had received drug addiction treatment, had shared needles or obtained syringes from mates, had never or only occasionally used condoms, and those reporting tuberculosis (TB), sexually transmitted disease (STD), or hepatitis B (HBV) infection. A large proportion of HIV-positive participants reported the final logistic regression model for reported HIV-positive status. These results are consistent with data provided by previous studies, which report HCV infection as one of the main health problems among IDUs, stabilization of the HIV infection rate, and an increase in co-infection by these viruses.

The highest incidences of HCV and HIV were reported by participants in a poorer social situation (lower educational level, widowed status, unemployed, informal and illegal activities, imprisoned) and those with a higher prevalence of other infectious diseases. Among the participants, 71% reported TB, HCV, HBV, HIV, or STD infection, and 43% had two or more of these diseases concurrently (data not presented). These results place intravenous drug use within a framework of social exclusion that goes hand in hand with a dramatic deterioration in health. The use of illicit drugs is one of the main causes of social exclusion, although many young people might already be considered socially excluded before they start to use drugs. Drug use and its associated problems form a part of a broader process that entails marginalization, vulnerability, and a lack of integration. All these issues are related to the health of IDUs and of those they interact with. Most interviewees in this study underwent some type of treatment for their drug use (79.9%), which suggests that treatment is available through the healthcare system and that IDUs have access to therapy and harm reduction advice. However, in general terms, the results are modest and treatment compliance rates are low, possibly because drug addicts must cope not only with

### Discussion

In this sample of socially excluded drug users who had injected drugs over the past year, we found a high prevalence of HCV infection, a relatively lower rate of HIV infection, and a high incidence of HCV infection among HIV-positive participants. These results are consistent with data provided by previous studies, which report HCV infection as one of the main health problems among IDUs, stabilization of the HIV infection rate, and an increase in co-infection by these viruses.

The highest incidences of HCV and HIV were reported by participants in a poorer social situation (lower educational level, widowed status, unemployed, informal and illegal activities, imprisoned) and those with a higher prevalence of other infectious diseases. Among the participants, 71% reported TB, HCV, HBV, HIV, or STD infection, and 43% had two or more of these diseases concurrently (data not presented). These results place intravenous drug use within a framework of social exclusion that goes hand in hand with a dramatic deterioration in health. The use of illicit drugs is one of the main causes of social exclusion, although many young people might already be considered socially excluded before they start to use drugs. Drug use and its associated problems form a part of a broader process that entails marginalization, vulnerability, and a lack of integration. All these issues are related to the health of IDUs and of those they interact with. Most interviewees in this study underwent some type of treatment for their drug use (79.9%), which suggests that treatment is available through the healthcare system and that IDUs have access to therapy and harm reduction advice. However, in general terms, the results are modest and treatment compliance rates are low, possibly because drug addicts must cope not only with
their addiction, but also with the process of social exclusion they are immersed in, i.e., unemployment, chronic disease, loss of emotional bonds, marginalization, and so on. To curb behavior that renders people more vulnerable to infection, action must be taken on a complex set of circumstances that require a multidisciplinary approach.

Hence, any course of action for these groups should, as far as possible, be built into integrated and coordinated...
plans that take a broad approach to the main issues involved.

The main form of HCV transmission among IDUs is by needle sharing, which is also among the main sources of HIV infection. Despite the recognized danger of this practice, sharing injecting equipment may continue among different generations of IDUs, and the reasons may remain unclear. Although fewer IDUs in this sample had shared needles over the past year (50.3%), those that did share needles showed a high prevalence of HCV and HIV. As in other studies, IDUs who had been in prison and continued injecting drugs had the highest prevalence of HCV and HIV. Sharing injection material, wherever it is done, is the true marker of HCV infection risk. Nevertheless, injecting drugs in prison worsens the situation, since very few prisons have syringe exchange programs, and this favors assiduous sharing of injection material. In addition, serving a prison sentence is often part of the marginalization process (toward or within), which may offer an integrated approach to the main issues in different generations of IDUs, and the reasons may remain unclear. HCV and HIV are very effectively transmitted through blood, long-lasting infections come to light, and this favors assiduous sharing of injection material. In addition, serving a prison sentence is often part of the marginalization process (toward or within), which may offer an integrated approach to addiction.

The high percentage of illicit drug users and the high incidence of infectious disease among prison populations increases the vulnerability of this population. This suggests that healthcare provision within prisons furnishes an extreme need for syringes showed a high prevalence of HCV and HIV. As in other studies, IDUs who had been in prison and continued injecting drugs had the highest prevalence of HCV and HIV. Sharing injection material, wherever it is done, is the true marker of HCV infection risk. Nevertheless, injecting drugs in prison worsens the situation, since very few prisons have syringe exchange programs, and this favors assiduous sharing of injection material. In addition, serving a prison sentence is often part of the marginalization process (toward or within), which may offer an integrated approach to the main issues in different generations of IDUs, and the reasons may remain unclear. HCV and HIV are very effectively transmitted through blood, long-lasting infections come to light, and this favors assiduous sharing of injection material. In addition, serving a prison sentence is often part of the marginalization process (toward or within), which may offer an integrated approach to addiction.

These results emphasize two major issues: first, the risk of infectious disease among prison populations increases the vulnerability of this population. This suggests that healthcare provision within prisons furnishes an extreme need for syringes showed a high prevalence of HCV and HIV. As in other studies, IDUs who had been in prison and continued injecting drugs had the highest prevalence of HCV and HIV. Sharing injection material, wherever it is done, is the true marker of HCV infection risk. Nevertheless, injecting drugs in prison worsens the situation, since very few prisons have syringe exchange programs, and this favors assiduous sharing of injection material. In addition, serving a prison sentence is often part of the marginalization process (toward or within), which may offer an integrated approach to the main issues in different generations of IDUs, and the reasons may remain unclear. HCV and HIV are very effectively transmitted through blood, long-lasting infections come to light, and this favors assiduous sharing of injection material. In addition, serving a prison sentence is often part of the marginalization process (toward or within), which may offer an integrated approach to addiction.

HIV infection and that there is a greater social stigma attached to this disease than to HCV, although both raise major barriers to social integration. Moreover, as HCV is very effectively transmitted through blood, long-lasting use of illicit drugs and an injecting habit may have a greater bearing on this disease than on HIV. This paper has several limitations, mainly due to the cross-sectional design, which does not enable inferences to be drawn in terms of causality. The study was carried out between 1998 and 2000; this may be a reason why the results differ from those of other studies.

sults might not reflect the present situation. In this work, HIV and HCV serology is self-reported. This prevents our knowing the ‘real’ status of the participants, and we should consider a potential bias related to memory failure or prejudices that can make declaration of these infections difficult. In addition, the way in which the question on hepatitis C was posed gives rise to a greater likelihood of false-negatives, i.e. people who have not been tested for HCV report they are HCV-free.

The considerable differences in HIV seroprevalence among cities in different countries could be due to a methodological bias. Nevertheless, some epidemiological studies indicate that there is considerable regional variation between and within countries in relation to HIV prevalence and incidence in IDUs. The percentages of HIV-seropositive individuals for each country in this study are reasonably within the ranges reported by other studies on the prevalence of HIV among IDUs. The differences observed could reflect a complex interaction between several factors, such as the patterns of drug consumption, how and when methadone treatment, preventive measures, and harm reduction programs were implemented, and the general HIV prevalence rates in each region.

It is important to highlight the large number of participants in this study that did not know their HIV or HCV serologic status. The reasons for this are difficult to determine, but it can be argued that socially excluded people tend to benefit less from social and health services. This situation can imply a bias in the results, by which there would be an underestimation of the seroprevalence of the sample. It is crucial to know the status of a target population for epidemiological vigilance and to plan preventive strategies adapted to the profiles of specific subpopulations. In addition, individuals who do not know whether they have a disease will not be able to benefit from the available treatments.

Despite these and other limitations, we believe that this study provides insight into the characteristics of IDUs reporting their HCV and HIV status in several European cities, and into the factors linked to these two diseases.
