Primary breast fibromatosis in a male
Fibromatosis mamaria en un hombre

Fernando Hernanz*, Jaime Jimeno, Lucia Paz, Andrés Güezmes

Breast Unit, Hospital Universitario Marqués de Valdecilla, Santander, Spain

A 41-year-old man presented with a painless left breast lump. Mamography with a core needle biopsy (immunohistochemical study) and axillary echography ruled out carcinoma and enlarged lymph nodes; the histologic study suggested a breast fibromatosis. He was operated on and a tumorectomy was carried out.

Fig. 1 demonstrates a composition of images: radiological (mamography and mammary echography), surgical procedure (lumpectomy) and macroscopical aspect of surgical specimen. The definitive pathological diagnosis was breast fibromatosis.

Mammary fibromatosis is a bizarre clinical entity, rarely reported in men,1 but poses significant diagnostic and therapeutic challenges.2 It usually presents with a palpable, firm, and painless mass that is difficult to differentiate from breast carcinoma based solely on the imaging approach.2

The optimal management is unknown owing to its rarity, a wide local excision with negative margins is considered the treatment of choice. There is a significant risk of local recurrence, but no metastasis potential, therefore there should be a strict follow-up of patients for at least three years.
